The capacity of pig uterine tissues to recognize and respond to maternal and conceptus signals determines whether pregnancy can be established and defines the environment in which embryonic and fetal growth occur. Limits of uterine capacity may be defined genetically. However, the extent to which functional uterine capacity approaches genetic potential may be determined, in part, by the success of organizational events associated with growth, morphogenesis and cytodifferentiation of uterine tissues. It is important, therefore, that these events be identified and evaluated with respect to their potential effect on adult uterine function. Histogenesis of the pig uterus begins prenatally, but is completed postnatally. Transformation of the uterine wall from histoarchitectural infancy to maturity occurs between birth and day 120. Morphogenetic events characteristic of the first 60 days of neonatal life proceed normally in gilts ovariectomized at birth. These events include appearance and proliferation of uterine glands, development of endometrial folds, and growth of the myometrium. Endometrial development during this period involves alterations in patterns of epithelial and stromal DNA synthesis, coordinated changes in the distribution and biosynthesis of extracellular matrix glycosaminoglycans and cell surface glycoconjugates, and specific alterations in patterns of uterine protein secretion. The ovary-independent, spatially coordinated nature of these events suggests that neonatal uterine development is regulated locally via dynamic cell–cell and cell–extracellular matrix interactions. The extent to which such potentially critical interactions must be preserved to ensure developmental success remains unknown. However, the normal pattern of ovary-independent cellular and molecular events associated with development of the uterine wall was disrupted by treating neonatal gilts with oestradiol valerate, and daily administration of oestrogen to gilts from birth to day 13 did not affect ovulation rate, but did reduce embryonic survival by 22% on day 45 of gestation in adults that were exposed to oestrogen neonatally. These observations support the idea that some organizational events associated with development of the neonatal uterine wall must be allowed to proceed without interruption to ensure that adult uterine function is not compromised. Efforts to identify specific developmental determinants of uterine capacity may be facilitated by examining the consequences of xenobiotically induced interruption of uterine development on adult uterine function. Such studies may also contribute to identification of uterine factors affecting embryonic survival and fetal growth.

Introduction

In pigs, establishment of pregnancy and maintenance of an embryotrophic uterine environment depend upon endometrial responses to both maternal and conceptus signals (Bazer, 1992). Thus, the ability of uterine tissues to recognize and integrate specific systemic and local signals determines whether pregnancy can become established and defines the environment in which embryonic and fetal growth occur. The quality of this environment dictates not only the number of conceptuses that can be supported at a specific stage of gestation in litter-bearing species such as pigs, but can also have profound effects on conceptus growth and postnatal phenotype (Christenson *et al.*, 1987; Roberts and Bazer, 1988; Cowley *et al.*, 1989; Pomp *et al.*, 1989; Atchley *et al.*, 1991). The extent to which uterine tissues function to optimize these traits contributes to uterine capacity (Christenson *et al.*, 1987; Bazer *et al.*, 1988).

The existence of hyperprolific breeds of pig, such as the Chinese Meishan, and development of strains such as the hyperprolific Large White (Legault, 1985), indicate that limits of uterine capacity may be defined genetically. Functionally, however, the observation that multiparous sows will carry more embryos to term than do gilts (Legault, 1985; First and Eyestone 1988) supports the idea that phenotypic uterine capacity may be determined, in part, by the developmental history of the uterus itself. This idea is reinforced by data indicating that adult urogenital tract function can be compromised if development is interrupted pharmacologically during fetal or early neonatal life (Sananes *et al.*, 1980; Forsberg, 1988; Mori and Iguchi, 1988; Halling and Forsberg, 1990). The success of organizational events associated with growth, morphogenesis and cytodifferentiation of uterine tissues may determine the potential of the adult uterus to respond to activational cues necessary to optimize prolificacy. Consequently, it is important that these events be defined and evaluated with respect to their potential to affect adult uterine function and reproductive efficiency.

Mechanisms regulating growth, development and differentiation of uterine tissues during fetal and neonatal periods are poorly defined for pigs, but may prove to be critical determinants of uterine capacity. The purpose of this report is to: (1) review events characteristic of early uterine development, (2) summarize recent observations pertaining to cellular and molecular events associated with normal uterine growth and development in neonatal pigs and (3) introduce data indicating that some neonatal developmental events may be required to proceed without interruption to ensure that adult porcine uterine function is not compromised.

Embryonic Origins, Growth and Histogenesis of the Pig Uterus

The uterus develops from the paramesonephric (Mullerian) ducts, a pair of completely mesodermal tubes that arise from invaginations of coelomic epithelium on the lateral aspects of the urogenital ridges (Marion and Gier, 1971; Cunha, 1989; Mossman, 1989). These ducts grow towards the midline, meet and begin to fuse at their caudal ends (Mossman, 1980). The degree of fusion that occurs is species specific and defines the gross morphological characteristics of the adult uterus (Davies, 1967; Mossman, 1980). In pigs complete caudal fusion of the paramesonephric ducts involves only a short segment of the ductal lumina. Consequently, the bicornuate pig uterus consists, grossly, of a short uterine body connecting long tubular uterine horns (Mossman, 1980, 1989).

Histologically, the endometrium and both inner circular and outer longitudinal smooth muscle layers of the myometrium develop from unorganized, undifferentiated mesenchyme (Marion and Gier, 1971; Brody and Cunha, 1989a). Organizational events leading to differentiation of the mesenchyme into endometrial and myometrial tissue layers, and development of relevant endometrial structure begin during fetal life and are completed postnatally in most species, including pigs. However, events characteristic of uterine histogenesis are ordered and include: (1) stratification and spatial orientation of subepithelial mesenchymal cells, leading to establishment of a dense subepithelial layer of stromal cells and a more loosely organized network of fibroblasts in the deeper stroma adjacent to the developing myometrium, (2) organization and differentiation of a prospective myometrium, and (3) coordinated development of species-specific endometrial histoarchitecture. Appearance and proliferation of coiled tubular uterine glands, characteristic of the endometrium in all viviparous mammals (Mossman, 1980), is a postnatal event in pigs. Development of the inner circular myometrial layer, derived from cells of the intermediate layer of ductal mesenchyme, precedes that of the outer longitudinal myometrium, which is

derived from subperimetrial mesenchyme (Bal and Getty, 1970; Marion and Gier, 1971; Mossman, 1980; Atkinson *et al.*, 1984; Konishi *et al.*, 1984; Wiley *et al.*, 1987; Brody and Cunha, 1989a).

Postnatal uterine growth and morphogenesis

Growth of the pig uterus and development of the uterine wall between birth (day 0) and puberty have been characterized grossly (Dyck, 1980; Dyck and Swierstra, 1983; Evans *et al.*, 1988; Wu and Dziuk, 1988) and histologically (Hadek and Getty, 1959; Bal and Getty, 1970; Erices and Schnurrbusch, 1979; Dyck, 1980; Spencer *et al.*, 1993a). Uterine wet weight increases slowly but linearly during the first 8–10 weeks of neonatal life, and is directly related to increasing age and body weight (Dyck and Swierstra, 1983). Thereafter, between day 60 and day 80, both uterine weight and uterine growth rate increase abruptly and continue to increase until near the time of puberty (Dyck, 1980; Dyck and Swierstra, 1983; Evans *et al.*, 1988; Wu and Dziuk, 1988). Dyck (1980) and Dyck and Swierstra (1983) suggested that the dramatic increase in uterine growth after approximately day 70 reflects uterotrophic effects of ovarian oestrogen. Peripheral plasma oestradiol concentrations increase during this period (Evans *et al.*, 1988). Consistent with these observations, Wu and Dziuk (1988) demonstrated that ovariectomy of neonatal gilts on day 20 did not affect uterine growth until after day 60, when uteri of intact controls were larger and grew more rapidly. These data were recently confirmed and extended by a study in which uteri ($n = 5$ per day) were obtained on days 0, 15, 30, 60, 90 and 120 from intact gilts and gilts ovariectomized on the day of birth (Bartol and Wiley, unpublished observations). Overall, uterine weight and both endometrial and myometrial thicknesses did not differ, and increased ($P < 0.01$) in a similar way in intact and ovariectomized gilts before day 60, but in intact gilts after day 60 these values were greater and increased ($P < 0.01$) more rapidly (Fig. 1). However, uteri of ovariectomized gilts did continue to grow until day 120. Wu and Dziuk (1988) also reported uterine growth for ovariectomized gilts between day 20 and day 140. Moreover, Evans *et al.* (1988) found no clear relationship between patterns of growth of adrenal or thyroid glands and gross aspects of reproductive tract growth in gilts between weaning at three weeks of age and puberty. These data suggest that growth of the pig uterus requires neither ovarian nor, possibly, adrenal or thyroid support between birth and day 60. However, patterns of uterine growth and histogenesis observed for gilts ovariectomized at or shortly after birth make it clear that extra-ovarian factors support these processes throughout the first 120–140 days of life.

Transformation of the pig uterine wall from histoarchitectural infancy to maturity occurs between birth and postnatal day 120 (Hadek and Getty, 1959; Bal and Getty, 1970; Erices and Schnurrbusch, 1979; Dyck and Swierstra, 1983). Dziuk and Gehlbach (1966) demonstrated that immature gilts that were induced to ovulate and bred artificially on or after neonatal day 110 could become pregnant and maintain corpora lutea for at least 23 days. Thus, uterine tissues not only become organized structurally, but also acquire the capacity to respond to conceptus signals during this period.

Significant remodelling of the pig uterine wall occurs during the first eight weeks of neonatal life (Fig. 2). Neither endometrial nor myometrial tissues are completely differentiated at birth (Bal and Getty, 1970). Endometrial glands, absent at birth, develop from shallow epithelial depressions, evident at intervals along the surface of the uterine lumen, into coiled, branched epithelial tubes that extend radially from the luminal surface, through endometrial stroma, to the adluminal border of the myometrium (Spencer *et al.*, 1993a). Uterine folds, evident by day 30 as luminal protrusions of glandular endometrium, are well developed by day 60 (Hadek and Getty, 1959; Bal and Getty, 1970; Spencer *et al.*, 1993a). A developing inner circular layer of myometrial cells is easily distinguished from endometrial stroma at birth; however, the outer longitudinal layer of smooth muscle is indistinct. Development of this layer lags behind that of the inner circular myometrium and proceeds in a cranial direction from the area of the uterine body toward the tips of the uterine horns (Bal and Getty, 1970). Overall, histoarchitectural features characteristic of the mature pig uterine wall are apparent, although not completely developed, by neonatal day 30 (Bal and Getty, 1970; Spencer *et al.*, 1993a).

Considered together, these observations indicate that extensive remodelling of the pig uterine wall occurs during a period associated with ovary-independent uterine growth. Similar patterns of ovary-independent uterine development were reported for the neonatal ewe by Bartol *et al.* (1988a,b), and for the mouse by others (Ogasawara *et al.*, 1983; Bigsby and Cunha, 1985). Data indicating that uterine histogenesis proceeds normally in neonatally ovariectomized, adrenalectomized mice were interpreted to

Fig. 1. Effects of ovariectomy (OVX) at birth (day 0) on (a) uterine wet weight, (b) endometrial thickness, and (c) myometrial thickness in crossbred gilts. Means (\pm SEM) are shown with best-fit, least-squares regressions for intact (\bullet —, $n = 5$ gilts per time point) and ovariectomized (\circ —, $n = 5$ gilts per time point) gilts.

Fig. 2. Representative photomicrographs illustrating patterns of histogenesis and distribution of glycosaminoglycans (GAGs) in the developing neonatal porcine uterine wall (a) and (b) at birth (day 0) and (c) and (d) on day 28 and (e) and (f) on day 56. Sections were stained together with either Mayer's haematoxylin and eosin (a, c, e), or Alcian blue-8GX in the presence of $0.1 \text{ mol MgCl}_2 \text{ l}^{-1}$ (b, d, f). Under these conditions, Alcian blue-8GX binds to both sulfated and unsulfated GAGs. Day 0: (a) note the slightly corrugated appearance of luminal epithelium (LE), organization of endometrial stroma (S), and state of development of the myometrium (M). Endometrial glands are absent. (b) Staining with Alcian blue-8GX is homogeneous. Day 28: (c) note presence of endometrial folds (arrowhead), glands (G) penetrating endometrial stroma (S), and development of the myometrium (M). (d) Note distinct zone of alcianophilia (arrowhead) in shallow stroma immediately beneath luminal epithelium (LE) and adjacent to the necks of developing uterine glands (G). Day 56: (e) endometrial folds (arrowhead) are well developed. Coiled, branched uterine glands (G) extend from the luminal surface (L) to the myometrium. Both inner circular (IC) and outer longitudinal (OL) myometrial smooth muscle layers are apparent and well developed. (f) Alcianophilia persists (arrowhead) in shallow stroma (S) immediately beneath luminal epithelium (LE). Uterine glands (G) are indicated. Scale bar (a) (d) = $50 \mu\text{m}$; (b) = $10 \mu\text{m}$; (c) (e) = $100 \mu\text{m}$.

indicate that early postnatal remodelling of the uterine wall occurs in an autonomous, developmentally programmed, steroid-independent manner (Ogasawara *et al.*, 1983; Bigsby and Cunha, 1985). However, endocrine signals necessary to initiate or facilitate early postnatal uterine developmental events may be generated at birth. Bartol *et al.* (1988a) demonstrated that endometrial gland development could be inhibited by chronic administration of a progestin to ovariectomized newborn lambs, and later could be allowed to proceed by removal of this artificial progestin block. Onset of uterine gland development in the neonate may, therefore, involve negative control. In this case, birth and the consequent removal of uterine tissues from a potentially inhibitory prenatal endocrine environment may provide a permissive signal(s) necessary to ensure normal postnatal uterine development. It remains to be determined whether such perinatal endocrine mechanisms affect development of the pig uterus.

Cellular and Molecular Characteristics of Neonatal Uterine Development

In a series of studies, Spencer *et al.* (1992b, 1993a) used uteri obtained by hysterectomy of crossbred neonatal pigs on day 0, 7, 14, 28, 42 and 56 to establish relationships between morphogenetic, cellular and molecular events characteristic of endometrial development during the period of postnatal life when ovarian factors are not essential for support of uterine growth and histogenesis. Autoradiography of uterine tissues, labelled *in vitro* with [methyl- ^3H]thymidine (^3H]Thd), revealed that transformation of the endometrium from an infantile, glandless state at birth, to a more nearly mature histoarchitectural state with onset of gland development, involved both age- and tissue site-specific changes in patterns of DNA synthesis (Spencer *et al.*, 1993a). ^3H]Thd labelling indices (LI) for both luminal epithelium and endometrial stroma were maximal at birth and decreased thereafter, although the decline in stromal ^3H]Thd LI was more gradual (Fig. 3). In contrast, glandular epithelial ^3H]Thd LI increased abruptly after birth and was maximal on days 7 and 14. Intense ^3H]Thd labelling was seen in association with epithelial cells in the tips and deeper lateral borders of developing endometrial glands (Fig. 4). Glandular epithelial ^3H]Thd LI increased in deeper endometrial zones with increasing age as glands grew into these regions of the uterine wall. Thus, as reported for neonatal sheep (Bartol *et al.*, 1988a) and mice (Ogasawara *et al.*, 1983; Bigsby and Cunha, 1985), pronounced, spatially focused increases in the proportion of epithelial cells actively synthesizing DNA and a more gradual decrease in stromal DNA synthesis were shown to accompany the appearance and proliferation of uterine glands in neonatal pigs.

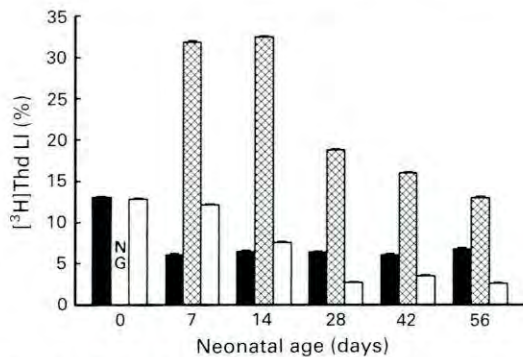

Fig. 3. Effects of neonatal age from birth (day 0) to day 56 on porcine endometrial [methyl- ^3H] thymidine (^3H]Thd) labelling index (LI) for (■) luminal epithelium, (▨) glandular epithelium and (□) stroma. Luminal epithelial LI was maximal at birth, decreased ($P < 0.01$) to day 7, and remained stable to day 56. In contrast, glandular epithelial LI was maximal on days 7 and 14 (day \times epithelial type $P < 0.01$) and declined thereafter. Uterine glands are absent at birth (NG). Stromal LI declined ($P < 0.01$) after day 0 to minimum values after day 14. Adapted from Spencer *et al.* (1993a).

Fig. 4. Representative photomicrographs illustrating the distribution of autoradiographic grains in uterine tissue sections from neonatal pigs labelled *in vitro* with [methyl- ^3H] thymidine (^3H]Thd). (a) Day 0 (birth): note distribution of nuclear labelling in luminal epithelium (LE) and stroma (S). (b) Day 14: note intense focal ^3H -Thd labelling in nuclei of glandular (G) compared with luminal epithelium (LE), and reduced labelling in stroma (S). Scale bars (a) = 10 μm ; (b) = 50 μm .

The observation that progressive, synchronous development of endometrial glands in neonatal pigs involves ovary-independent, temporal and spatial regulation of epithelial DNA synthesis is consistent with the idea that this process is regulated locally. Such local regulation could be achieved via mechanisms that support the establishment of unique, zonally variable tissue microenvironments (Padykula *et al.*, 1984, 1989; Sugimura *et al.*, 1986; Spencer *et al.*, 1993a). Developmentally critical tissue microenvironments are likely to become established as a consequence of interactions between epithelium and underlying mesenchyme or stroma. Reciprocal interactions between these tissue compartments support both morphogenesis and differentiation of many tissues, including those of the uterus (Cunha and Lung, 1979, Cunha *et al.*, 1983, 1989; Sanders, 1988; Sharpe and Ferguson, 1988; Bigsby, 1991). Studies of murine uterine tissues indicate that mesenchyme is required to direct and specify patterns of epithelial development, whereas epithelium is required to support or direct organization and differentiation of endometrial stroma as well as myometrial organization and growth (Cunha *et al.*, 1983, 1989; Brody and Cunha, 1989a; Bigsby, 1991; Wegner and Carson, 1992). Dynamic reciprocal interactions of this kind provide a system for local control and coordination of developmentally important epithelial and stromal cell behaviours including proliferation, movement, adhesion and differentiation (Sharpe and Ferguson, 1988; Brody and Cunha, 1989a,b; Cunha *et al.*, 1989; Wegner and Carson, 1992). Mechanisms through which permissive or inductive stimuli are communicated between epithelial and stromal compartments have not been precisely defined. However, spatially focused developmental events may not only reflect,

but may also be coordinated by, alterations in the tissue microenvironment produced through independent and synergistic effects of components of the extracellular matrix (ECM) and diffusible morphogens (Flaumenhaft and Rifkin, 1991; Jackson *et al.*, 1991; Ettinger and Doljanski, 1992; Schubert, 1992).

The ECM, glycosaminoglycans and local control of uterine wall development

Glycosaminoglycans (GAGs), including hyaluronic acid (HA), and the sulfated GAGs (SGAGs) chondroitin sulfate (CS, including dermatan sulfate), heparan sulfate (HS) and keratan sulfate, are negatively charged, complex carbohydrates that, with the exception of HA, are found as components of proteoglycans in the ECM (Jackson *et al.*, 1991). Through their ability to affect cell behaviour directly and to mediate access of growth factors or other diffusible morphogens to target cells, GAGs can have profound effects on morphogenetic and cytodifferentiative events in developing tissues and organs (Cunha and Lung, 1979; Bernfield, 1981; Toole, 1991; Ettinger and Doljanski, 1992). Reciprocal interactions between cell compartments in developing epithelial–mesenchymal organs, such as the uterus, produce alterations in tissue GAG biochemistry that, in turn, affect cell behaviour in both compartments (Cunha and Lung, 1979; Hayashi *et al.*, 1982; Bissell and Barcellos-Hoff, 1987; Ettinger and Doljanski, 1992). Thus, both cell–cell and cell–ECM interactions contribute to the establishment and evolution of dynamic physical and biochemical conditions in which local developmental events occur.

When neonatal pig uterine tissues obtained between birth and day 56 were stained with Alcian Blue-8GX (AB), a distinct pattern of stromal GAG distribution was seen in clear temporal and spatial association with the appearance and proliferation of endometrial glands (Spencer *et al.*, 1993a). A GAG-rich alcianophilic zone, which was not present at birth, was observed in the shallow stroma of uteri from day 7 and later. Staining was most intense at the epithelial–mesenchymal interface and in stromal areas immediately adjacent to luminal epithelium and surrounding the necks of developing endometrial glands (Fig. 2). Staining characteristic of SGAGs persisted in those areas adjacent to epithelium where [³H]Thd LI was minimal (Spencer *et al.*, 1993a). Similar relationships were reported for the developing ovine uterus (Bartol *et al.*, 1988a,b).

Autoradiography of D-[6-³H]glucosamine-([³H]GlcN)-labelled pig uterine tissues obtained between birth and day 56 revealed significant incorporation of this GAG precursor into the stroma (Spencer *et al.*, 1993a). Labelling with [³H]GlcN was most intense in shallow, subepithelial stroma at birth and declined thereafter as zonal AB staining became apparent and glandular epithelial DNA synthesis increased (Fig. 5). Products of pig uterine [³H]GlcN metabolism have yet to be identified *in situ*. However, neonatal uterine tissues can synthesize GAGs from [³H]GlcN *in vitro* (Bartol *et al.*, 1992; Wiley *et al.*, 1992). When GAGs extracted from uterine tissues obtained on days 7, 14 and 49 were subjected to DEAE anion exchange chromatography as described by Bellin and Ax (1987), three major DEAE-positive peaks of [³H]GlcN-labelled material were identified. On the basis of the elution positions of these peaks relative to authentic GAG standards and the sensitivity of labelled material in individual peaks to digestion with *Streptomyces* hyaluronidase (EC 4.2.2.1), HNO₂ and chondroitinase ABC (EC 4.2.2.4), it was determined that uterine tissues produced HA, HS and CS from [³H]GlcN substrate (Fig. 6). Moreover, the proportion of newly synthesized GAG identified as SGAG (HS and CS) increased after day 7, whereas relative production of HA decreased (Bartol *et al.*, 1992).

Data indicate that GAGs are actively synthesized by pig uterine tissues at birth and accumulate in endometrial stroma and at the epithelial–mesenchymal interfaces where an SGAG-rich zone is established and maintained beneath morphogenetically stable areas of uterine epithelium. Similar relationships have been reported for other developing epithelial–mesenchymal organs (Cunha and Lung, 1979; Bernfield, 1981; Hayashi *et al.*, 1982; Silberstein and Daniel, 1982). Site-specific, epithelial–mesenchymal interactions may alter patterns of synthesis and deposition of GAGs and produce changes in local microenvironmental conditions that are necessary to facilitate epithelial mitotic activity and genesis of endometrial glands, as well as more subtle cytodifferentiative events associated with maturation of the uterine wall (Hayashi *et al.*, 1982; Spooner and Thompson-Pletscher, 1986; Jackson *et al.*, 1991; Spencer *et al.*, 1993a). Direct interactions of GAGs with cell surface binding domains can affect cell proliferation, mRNA stability and patterns of protein synthesis, and may determine whether cells are competent to respond to growth factors (Bissell and Barcellos-Hoff, 1987; Jackson *et al.*, 1991; Schubert, 1992; Kan *et al.*,

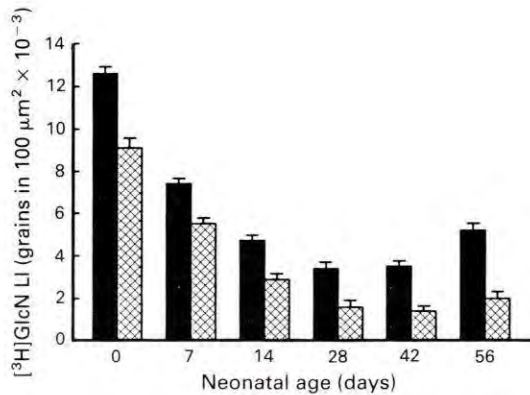

Fig. 5. Effects of neonatal age, from birth (day 0) to day 56, on D-[6-³H] glucosamine (³H]GlcN) labelling index (LI; grains in 100 μm² × 10⁻³) for porcine endometrial stroma. LI was determined for (■) shallow and (▨) deep stromal zones. Shallow stroma was defined to include that area extending 100 μm (50 μm in uteri from day 0) from the basal aspect of the luminal epithelium. Deep stroma was defined as that area extending 100 μm (50 μm in uteri from day 0) adluminally from the interface of the inner circular layer of developing myometrium and the endometrial stroma. Overall, stromal ³H]GlcN LI was greater for shallow than for deep stroma ($P < 0.01$), maximal in both zones at birth, and decreased curvilinearly to minimum values on days 28 and 42 (cubic effect of day, $P < 0.01$). However, LI increased in shallow stroma from day 28 to day 56 (day × stromal zone, $P < 0.03$). Uteri were obtained by hysterectomy of neonatal gilts on days 0 ($n = 4$), 7 ($n = 5$), 14 ($n = 5$), 28 ($n = 3$), 42 ($n = 6$) and 56 ($n = 3$). Adapted from Spencer *et al.* (1993a).

1993). When taken into cells, GAGs may affect second messenger systems by altering calcium dynamics, protein kinase activity and intranuclear events that determine whether cells can traverse the cell cycle (Jackson *et al.*, 1991). Equally important, GAGs can bind polypeptide growth factors specifically and nonspecifically (Flaumenhaft and Rifkin, 1991). Consequently, diffusible growth factors or other morphogens may be (1) trapped or concentrated within ECM zones and prevented from gaining access to target cells, (2) protected from proteolytic degradation and presented directly to nearby target cells or cells that migrate into the factor-rich zone, or (3) released to act on target cells following ECM degradation (Flaumenhaft and Rifkin, 1991; Schubert, 1992). Thus, the ability of endometrial tissues to affect temporal and spatial alterations in the nature and distribution of GAGs may represent an important mechanism for local regulation and coordination of uterine morphogenetic and cytodifferentiative events.

Marker-coupled lectins have been used to identify specific carbohydrate residues that could mediate interactions of cells with other cells, the ECM, and growth factors during the course of development of many organs including the uterus (Bartol *et al.*, 1988b; Aplin, 1991; Spencer *et al.*, 1992b; Spicer and Schulte, 1992). A histochemical study of the distribution of endometrial lectin-binding sites in neonatal porcine uteri (Spencer *et al.*, 1992b) revealed that binding patterns for three lectins, including ConA (specificity: α-D-mannose and α-D-glucose), RCA-I (specificity: β-D-galactose and β-N-acetyl-D-galactosamine), and UEA-I (specificity: α-L-fucose) changed in an age-related manner between birth and day 56. Binding patterns observed for RCA-I were unique. Staining with this lectin was homogeneous for luminal epithelium but distinctly variegated for glandular epithelium (Fig. 7), indicating that there

Fig. 6. Representative DEAE anion exchange chromatogram showing elution positions of major D-[6-³H] glucosamine (³H]GlcN)-labelled, lipid- and protein-free, potassium acetate precipitable glycosaminoglycans (GAGs) extracted from neonatal porcine uterine tissue obtained on postnatal day 49. Three major peaks of [³H]GlcN-labelled material were consistently identified when GAGs extracted from uterine tissues obtained on days 7, 14 or 49 were applied to an HPLC DEAE 5PW anion exchange column and eluted with a linear NaCl gradient (.....) as described by Bellin and Ax (1986). On the basis of (1) the elution positions of these peaks relative to authentic GAG standards including hyaluronic acid (HA), heparan sulfate (HS), and chondroitin sulfate (CS), and (2) the sensitivity of labelled material in individual peaks to digestion with *Streptomyces* hyaluronidase (EC 4.2.2.1), HNO₂ and chondroitinase ABC (EC 4.2.2.4), uterine tissues were determined to produce HA, HS and CS from [³H]GlcN substrate. Data are presented as a percentage of total ³H-labelled material loaded on to the column.

are alterations in the distribution or orientation of β -D-galactose and (or) β -N-acetyl-D-galactosamine residues associated with these cells. Phenotypic variations of this kind may reflect altered production of glycosidases and glycosyltransferases, or changes in the structure of core proteins to which carbohydrates attach (Spicer and Schulte, 1992). These data provide additional evidence that local conditions support spatially unique development of specific endometrial cell populations.

Neonatal uterine proteins

When proteins produced from radiolabelled amino acid substrate by tissues maintained in organotypic culture are separated by two-dimensional PAGE and visualized fluorographically, the result is a two-dimensional PAGE 'fingerprint' that defines the functional characteristics or state of differentiation of that tissue (Cunha *et al.*, 1983). These procedures have been used to identify molecular markers of normal and aberrant murine urogenital tract development (Carter *et al.*, 1982; Newbold *et al.*, 1984; Maier *et al.*, 1985) and were applied recently in studies of the developing pig uterus (Bartol *et al.*, 1991; Christenson *et al.*, 1992; Vallet *et al.*, 1992; Spencer *et al.*, 1993b). Attention has been focused on the array of proteins produced by porcine neonatal uterine tissues from L-4-5-[³H]leucine ([³H]Leu) and released into explant medium. This set of proteins and polypeptides is likely to represent the array of uterine secretory products with potential for extracellular diffusion and, therefore, may include locally produced morphogens that affect the developmental behaviour of constituent cell populations. Proteins and polypeptide growth factors from the uterus have been implicated in mechanisms regulating adult ovine (Ikeda and Sirbasku,

Fig. 7. Representative photomicrograph of the neonatal porcine uterine wall in cross-section illustrating the distribution of endometrial lectin binding sites (dark areas) for RCA-I (carbohydrate specificity: β -D-galactose and β -*n*-acetyl-D-galactosamine). Note distinct variegated staining pattern in glandular (G) as compared to luminal (L) epithelium. Example from neonatal day 14. Scale bar = 10 μ m.

Fig. 8. Fluorograph of a two-dimensional PAGE gel illustrating the array of proteins and polypeptides produced from [3 H]leucine and released into explant medium by neonatal porcine uterine tissue obtained on day 14. Proteins were separated by isoelectric point (pI) in the first dimension and by molecular weight ($M_r \times 10^{-3}$) in the second dimension using SDS-PAGE (12.5% total acrylamide monomer).

1984; Bird *et al.*, 1988; Reynolds *et al.*, 1990) and porcine (Brigstock *et al.*, 1989; Simmen *et al.*, 1988, 1989b) uterine growth and function.

Tissues obtained from neonatal gilts during the ovary-independent period of uterine growth produce complex arrays of proteins from [3 H]Leu (Fig. 8) that reflect the age and (or) histoarchitectural state of the uterine wall (Bartol *et al.*, 1991; Christenson *et al.*, 1992; Vallet *et al.*, 1992; Spencer *et al.*, 1993b). Consistent with observations of the effects of ovariectomy at birth on uterine growth and histogenesis mentioned above, preliminary observations suggest that patterns of uterine protein secretion do not differ between intact and ovariectomized gilts before neonatal day 60 (F. Bartol, A. Wiley and J. McGee,

unpublished observations). Thus, both uterine morphogenetic and cytodifferentiative events characteristic of this period appear to proceed in an ovary-independent manner.

In a comparative study of uterine morphogenesis and protein secretion in hyperprolific Meishan ($n = 22$) and White crossbred ($\frac{1}{4}$ each Chester White, Landrace, Large White and Yorkshire) gilts ($n = 35$), uteri were obtained at necropsy on day 1, 14, 28, 42 or 56 (birth = day 0). Uterine weights were similar and increased in both breeds from day 1 to day 42, but differed on day 56 (day \times breed, $P < 0.01$) when ovarian (0.2 ± 0.1 versus 1.4 ± 0.1 g) and uterine (3.9 ± 0.2 versus 8.4 ± 0.2 g) weights were greater and endometrial gland development was advanced in Meishan gilts (Christenson *et al.*, 1992). Marked uterine growth and development occurred in both Meishan and crossbred gilts between day 1 and day 42, before differences in ovarian weights were observed. Uterine secretion of at least three [3 H]Leu-labelled proteins ($\sim M_r \times 10^{-3}$ /pI: 45/6.0, 25/6.2, 20/5.5) increased in clear temporal association with uterine gland development during this period in both breeds. However, secretion of a fourth protein ($\sim M_r \times 10^{-3}$ /pI: 97/4.0) increased by day 28 in Meishan gilts only, and a fifth ($\sim M_r$ /pI: 13/6.0) increased by day 56 in crossbred gilts only. General mechanisms regulating uterine development are likely to be highly conserved (Cunha *et al.*, 1983). However, identification of breed-specific differences in patterns of neonatal uterine protein secretion between hyperprolific Meishan and White crossbred gilts provides indirect support for the idea that developmental events may affect adult uterine capacity.

Local morphoregulatory roles for individual proteins produced by neonatal uterine tissues remain to be defined. However, Vallet *et al.* (1992) demonstrated that one of these proteins ($\sim M_r \times 10^{-3}$ /pI: 20/5.5) is physically and immunochemically related to retinol-binding protein (RBP) produced by the endometrium of adult pigs (Adams *et al.*, 1981; Trout *et al.*, 1992). When [3 H]Leu-supplemented medium conditioned with neonatal porcine uterine tissues from day 0, 3, 6, 9 or 12 was subjected to quantitative immunoprecipitation with anti-human RBP antiserum (Dako, Carpinteria, CA) and precipitated material was subjected to SDS-PAGE, fluorography revealed two immunoreactive protein bands ($\sim M_r \times 10^{-3}$: 19 and 20). Densitometric analyses indicated that secretion of the major 20 000 M_r product increased from birth to day 3 and remained stable until day 12, while secretion of the minor 19 000 M_r product decreased after day 6 (Vallet *et al.*, 1992 and unpublished observations). Thus, uterine secretion of an immunoreactive RBP-like protein increases in association with the appearance and proliferation of endometrial glands and progressive development of the myometrium. Given the importance of retinoids as morphogens and in mediation of epithelial-mesenchymal interactions and epithelial maturation (Wedden, 1987; De Luca, 1991), increased production of RBP may be necessary to ensure that retinol dynamics are adequately regulated in the developing uterine wall. However, structural and functional similarities between RBP and chick purpurin – a neural cell adhesion-mediating protein that has 50% amino acid sequence homology with human RBP (Pervaiz and Brew, 1987) and displays retinol-binding activity (Schubert and LaCorbiere, 1986) – suggest that RBP could also act directly to promote cell-cell or cell-substratum interactions associated with uterine remodelling. Since adhesion-promoting properties of such molecules are affected by specific GAGs (Jackson *et al.*, 1991), the role, if any, of RBP in mediation of uterine wall development may change in association with alterations in the quality of the ECM.

Consequences in the Adult of Interruption of Uterine Development

A method for interruption of the normal programme of uterine development is needed in order to test the hypothesis that uterine organizational events must proceed without interruption to ensure adult uterine competence. The idea that interruption of development during specific 'critical' periods could have lasting effects on tissue form and function is not new (Stockard, 1921). Accordingly, exposure of fetal and neonatal rodents to oestrogens or related xenobiotics was shown to reduce fertility and to produce a variety of structural and functional lesions in adult uterine tissues, including cystic endometrial hyperplasia, squamous metaplasia, adenomyosis, myometrial hypoplasia, reduced concentrations of oestrogen and progesterone receptors, altered steroid metabolism and responsiveness, and altered protein synthesis (Newbold *et al.*, 1984; Branham *et al.*, 1985a,b, 1988a,b,c; Forsberg, 1988; Medlock *et al.*, 1988; Mori and Iguchi, 1988; Halling and Forsberg, 1990). It therefore seems reasonable to propose that oestrogen might be a useful tool with which to interrupt uterine development in neonatal pigs.

Studies were conducted to determine effects of oestradiol valerate ($50 \mu\text{g kg}^{-1}$ bodyweight day $^{-1}$, i.m.), administered during specific periods of neonatal life associated with ovary-independent uterine development, on patterns of uterine growth, histogenesis and protein secretion (Spencer *et al.*, 1993b), GAG synthesis (Bartol *et al.*, 1992), and steady-state concentrations of insulin-like growth factor I (IGF-I) mRNA (Spencer *et al.*, 1992a). For these studies, crossbred gilts (3 to 5 per group) received either corn oil vehicle or oestradiol valerate for seven consecutive days from either birth to day 6, day 7 to day 13, or day 42 to day 48, before hysterectomy on day 7, 14 or 49, respectively. Treatment intervals were chosen to coincide with infantile (<day 7), proliferative (days 7–14), and growth (>day 14) periods of endometrial development that were defined on the basis of gross, histological and biochemical characteristics of the developing uterine wall described above and elsewhere (Spencer *et al.*, 1992b, 1993a,b).

The possibility that IGF-I is involved in normal porcine uterine development, or in mediation of uterine responses to oestrogen, is significant. IGF-I production is regulated developmentally in many tissues (D'Ercole *et al.*, 1984; Lund *et al.*, 1986; Simmen *et al.*, 1989a). This growth factor is mitogenic for a number of cell types (Zapf and Froesch, 1986), including porcine endometrial cells (Simmen *et al.*, 1989a) promotes cellular differentiation (Simmen *et al.*, 1989a), and stimulates incorporation of sulfate into GAGs (Adashi *et al.*, 1986). Although not established for the neonate, IGF-I receptors are present in (Hofig *et al.*, 1991), and IGF binding proteins are produced by (Simmen and Simmen, 1990; Simmen *et al.*, 1991) the adult pig uterus. In the immature and adult rat and pig, oestrogen-induced uterine growth and differentiation are accompanied by increased uterine production of IGF-I (Murphy and Ghahary 1990; Simmen *et al.*, 1990; Carlsson and Billig, 1991). Thus, IGF-I could be an autocrine or paracrine mediator of oestrogen action. In pigs (Lee *et al.*, 1991) and other species (Daughaday and Rotwein, 1989), circulating concentrations of IGF-I increase postnatally in association with maturation of the somatotrophic axis. Consequently, IGF-I may also act in an endocrine fashion to influence uterine development in the neonate.

Table 1. Effects of oestradiol valerate^a, administered to neonatal gilts during infantile (days 0–6), proliferative (days 7–13) or growth (days 42–48) periods, on uterine wet weight, endometrial thickness, and myometrial thickness on neonatal days 7, 14 and 49

Day	Uterine wet weight (g)		Endometrial thickness (μm)		Myometrial thickness (μm)	
	CO ^b	EV ^c	CO	EV	CO	EV
7	1.1 \pm 0.3 ^a	2.8 \pm 0.3 ^a	282 \pm 59 ^a	412 \pm 49 ^a	222 \pm 19 ^a	252 \pm 18
14	1.0 \pm 0.3 ^a	3.2 \pm 0.3 ^a	281 \pm 49 ^a	525 \pm 42 ^a	204 \pm 18 ^a	221 \pm 16
49	9.8 \pm 2.0 ^b	41.5 \pm 2.0 ^a	815 \pm 49 ^b	1535 \pm 43 ^a	321 \pm 18 ^b	911 \pm 16 ^a

^aNeonatal gilts ($n = 22$) were treated with either oestradiol valerate (EV, $50 \mu\text{g kg}^{-1}$ body weight day $^{-1}$) or corn oil vehicle (CO) daily for 7 days before hysterectomy on either day 7 (n : CO = 3, EV = 4), 14 (n : CO = 3, EV = 5) or 49 (n : CO = 3, EV = 4). Adapted from Spencer *et al.* (1993b).

^bFor CO data, values in the same column with different superscripts are significantly different ($P < 0.01$).

^cWithin each day, significant ($P < 0.01$) effects of oestradiol valerate are denoted by (*). Day \times treatment interactions ($P < 0.01$) were detected for all responses.

Treatment of neonatal gilts with oestradiol valerate increased uterine wet weight and endometrial thickness in all periods, while myometrial thickness increased following treatment during the growth period only (Table 1). Histologically, uteri of all gilts treated with oestradiol valerate displayed precocious development of endometrial glands and folds (Spencer *et al.*, 1993b). Both gross and histological responses to oestradiol valerate were most pronounced following treatment during the growth period. Measurement of radioactivity associated with $^{25}[\text{H}]\text{Leu}$ -labelled uterine proteins identified by two-dimensional PAGE revealed that treatment with oestradiol valerate during infantile, proliferative and growth periods affected production of three, eight, and 14 individual proteins, respectively (Spencer *et al.*,

1993b). Overall, oestradiol valerate decreased the percentage of total [^3H]GlcN-labelled uterine GAG identified by HPLC DEAE anion exchange chromatography as HA (control versus oestradiol valerate treated: 62.3% > 51.5%, SEM = 1.2, $P < 0.01$) and increased that identified as SGAG (Bartol *et al.*, 1992), including HS (12.9% < 15.0%, SEM = 0.5, $P < 0.05$), and CS (24.8% < 33.6%, SEM = 1.3%, $P < 0.01$). Northern hybridization analysis of poly(A) $^+$ RNA isolated from neonatal uteri obtained from both control and oestradiol valerate-treated gilts using porcine IGF-I cDNA probe Sigf.3 (Tavakkol *et al.*, 1988) revealed a single 1.2 kb transcript. Consistent with observations reported for the neonatal rat (Carlsson and Billig, 1991), steady-state concentrations of pig uterine IGF-I mRNA decreased ($P < 0.01$) after day 7 (relative absorbance units for days 7, 14 and 49: 7.8, 4.7 and 5.2; SEM = 0.4). However, treatment with oestradiol valerate increased ($P < 0.01$) uterine IGF-I mRNA levels by 1.4 times compared with controls. In addition, peripheral plasma concentrations of IGF-I increased ($P < 0.01$) linearly with age from day 7 to day 49 (means for days 7, 14 and 49: 28.6, 34.3 and 50.4 ng ml $^{-1}$; SEM = 2.3) and following treatment with oestradiol valerate ($P < 0.02$), regardless of when exposure occurred (control versus oestradiol valerate treated: 37.8 < 51.1 ng ml $^{-1}$, SEM = 3.8; Spencer *et al.*, 1992a).

These studies demonstrated clearly that oestradiol valerate can be used to disrupt the normal programme of physical, biochemical and endocrine events associated with development of the pig uterine wall. Responses of the neonatal uterus to oestradiol valerate can be interpreted to indicate that (1) uterine tissues are sensitive to oestrogen, (2) acquisition of oestrogen sensitivity occurs progressively in the developing uterine wall, as reported for other species (Katzenellenbogen, 1979; Kaye, 1983; Pasqualini and Sumida, 1986), and (3) oestrogen-sensitive pig uterine cell populations develop first in the endometrium (Spencer *et al.*, 1993b). In addition, effects of oestradiol valerate on uterine growth, histoarchitecture and patterns of protein secretion are unique to the periods when oestrogen exposure occurs (Spencer *et al.*, 1993b). Such period-specific responses may reflect (1) the size and nature of uterine cell populations competent to respond to oestrogen, or soluble mediators of oestrogen action such as IGF-I, and (2) the consequences of oestrogen-induced aberrations in epithelial:mesenchymal ratio and related changes in patterns of cell-cell and cell-ECM interactions, through which both tissue form and function are likely to be determined (Bissell and Barcellos-Hoff, 1987; Ettinger and Doljanski, 1992; Spencer *et al.*, 1993b). As the ability of uterine cells to respond to xenobiotic or natural organizational signals can change with time, and may also be determined by physico-chemical relationships that exist or develop between cells or between cells and their associated ECM, even subtle alterations in local microenvironmental conditions may have profound effects on the developmental fate of uterine tissues (Taguchi *et al.*, 1988; Ettinger and Doljanski, 1992).

Recently, a study was conducted to determine whether oestradiol valerate-induced interruption of uterine development during the first two weeks of neonatal life, the period when effects of oestradiol valerate on uterine histoarchitecture were confined to the endometrium (Spencer *et al.*, 1993b), would affect reproductive performance in adult pigs. Gilts treated with either oestradiol valerate (50 $\mu\text{g kg}^{-1}$ body weight day $^{-1}$, i.m.; $n = 8$) or corn oil ($n = 9$) daily, from birth to day 13, were allowed to reach puberty and were mated naturally at their second oestrus. Treatment did not affect the ability of adults to cycle or conceive, and did not affect ovulation rate as reflected by the number of corpora lutea (16 \pm 0.5) identified on the ovaries of oestradiol valerate- and corn oil-treated gilts at necropsy on day 45 of gestation. However, neonatal oestradiol valerate treatment reduced ($P < 0.08$) the number of potentially viable conceptuses per gilt (oestradiol valerate = 8.9 < corn oil \times 11.8, SEM = 1.0), and increased ($P < 0.01$) the percentage of total conceptuses identified as necrotic or deformed (oestradiol valerate = 17.1 > corn oil = 1.0, SEM = 3.5%). The proportion of animals with necrotic conceptuses was 1 of 9 for control gilts, in which a single necrotic conceptus was found, and 7 of 8 for oestradiol valerate treated gilts, in which 11 necrotic conceptuses and two grossly malformed fetuses were identified. Embryonic survival, expressed as the proportion of corpora lutea, represented by viable conceptuses on gestational day 45, was reduced ($P < 0.05$) by 22% in neonatally oestradiol valerate-treated gilts (oestradiol valerate = 54.5 < control = 76.9, SEM = 6.9%).

Conclusion

Data indicate that events sensitive to oestradiol valerate-induced perturbation during the first two weeks of neonatal life may be required to proceed without interruption to ensure that adult porcine uterine

capacity is not compromised. More generally, results support the hypothesis that the ability of adult uterine tissues to recognize and integrate signals necessary for establishment and maintenance of pregnancy in pigs (Bazer, 1992) may be determined, in part, by the degree of success realized during critical periods of uterine development.

Data reviewed herein suggest that critical uterine developmental events may be regulated locally, through dynamic, reciprocal, cell-cell and cell-ECM interactions, and underscore the importance of efforts to delineate these mechanisms. To this end, use of oestrogens or other natural or xenobiotic agents as tools with which to manipulate uterine developmental events and induce definable lesions in adult uterine tissues may provide strategies for identification of both developmental and functional determinants of uterine capacity in pigs.

The authors thank F. W. Bazer (Texas A&M University) and R. C. M. Simmen (University of Florida) for valuable discussions and technical collaboration that have contributed significantly to development of this research.
